

Monetary Policy, Redistribution, and Risk Premia*

Rohan Kekre[†] Moritz Lenel[‡]

April 2022

Abstract

We study the transmission of monetary policy through risk premia in a heterogeneous agent New Keynesian environment. Heterogeneity in households' marginal propensity to take risk (MPR) summarizes differences in portfolio choice on the margin. An unexpected reduction in the nominal interest rate redistributes to households with high MPRs, lowering risk premia and amplifying the stimulus to the real economy. Quantitatively, this mechanism rationalizes the role of news about future excess returns in driving the stock market response to monetary policy shocks and amplifies their real effects by 1.3-1.4 times.

1 Introduction

A growing literature finds that expansionary monetary policy lowers risk premia. This has been established for the equity premium in stock markets, the term premium in nominal bonds, and the external finance premium on risky corporate debt.¹ The basic New Keynesian framework as in Woodford (2003) and Gali (2008) does not capture this aspect of monetary policy transmission. As noted by Kaplan and Violante (2018), this is equally true for emerging heterogeneous agent New Keynesian models in which heterogeneity in the marginal propensity to consume enriches the transmission mechanism but still cannot explain the associated movements in risk premia.

This paper demonstrates that a New Keynesian model with heterogeneous households differing instead in risk-bearing capacity can quantitatively rationalize the observed effects of policy on risk premia, amplifying the transmission to the real economy. An expansionary monetary policy shock lowers the risk premium on capital if it redistributes to households with a high marginal propensity to take risk (MPR), defined as the marginal propensity to save in capital relative to save overall. With heterogeneity in risk aversion, portfolio constraints, rules of thumb, background risk, or beliefs, high MPR households borrow in the bond market from low MPR households to hold leveraged positions in capital. By generating unexpected inflation, raising profit income relative to labor income, and raising the price of capital, an expansionary monetary policy shock redistributes to high MPR households and thus lowers the market price of risk. In a calibration matching portfolio heterogeneity in the U.S. economy, this rationalizes the observed role of news about lower future excess returns in driving the increase in the stock market. The real stimulus is amplified by 1.3-1.4 times relative to an economy without heterogeneity in portfolios and MPRs.

Our baseline environment enriches a standard New Keynesian model with Epstein and Zin (1991) preferences and heterogeneity in risk aversion. Households consume, supply labor subject to adjustment costs in nominal wages, and choose a portfolio of nominal bonds and capital. Production is subject to aggregate TFP shocks. Monetary policy follows a Taylor (1993) rule. Heterogeneity in risk aversion generates heterogeneity in MPRs and exposures to a monetary policy shock. Epstein-Zin preferences imply that this heterogeneity is distinct from households' intertemporal elasticities of substitution. We first analytically characterize the effects of a monetary policy

¹See Bernanke and Kuttner (2005), Hanson and Stein (2015), and Gertler and Karadi (2015).

shock in a simple two-period version of this environment, providing an organizing framework for the quantitative analysis of the infinite horizon which follows.

An expansionary monetary policy shock lowers the risk premium by redistributing wealth to households with a high marginal propensity to save in capital relative to save overall — that is, a high MPR. Redistribution to high MPR households lowers the risk premium because of asset market clearing: if households on aggregate wish to increase their portfolio share in capital, its expected return must fall relative to that on bonds. An expansionary monetary policy shock redistributes across households by revaluing their initial balance sheets: it deflates nominal debt, raises the profits earned using capital, and raises the price of capital. More risk tolerant households hold leveraged positions in capital and have a higher MPR. Hence, an expansionary monetary policy shock will redistribute to these households and lower the risk premium.

The reduction in the risk premium amplifies the transmission of monetary policy to the real economy. Conditional on the real interest rate — which reflects the degree of nominal rigidity and the monetary policy rule — a decline in the required excess return on capital is associated with an increase in investment. The increase in investment crowds in consumption by raising household wealth. The stimulus to consumption and investment implies an increase in output overall.

These results are robust to heterogeneity beyond risk aversion. We consider a richer environment in which households may also face portfolio constraints or follow rules-of-thumb; households may be subject to idiosyncratic background risk; and households may have subjective beliefs regarding the value of capital. Because each of these still imply that households holding more levered positions in capital will be those with high MPRs, they continue to imply that expansionary monetary policy will lower the risk premium through redistribution, amplifying real transmission.

Accounting for the risk premium effects of monetary policy is important given empirical evidence implying that it may be a key component of the transmission mechanism. We refresh this point from Bernanke and Kuttner (2005) using the structural vector autoregression instrumental variables (SVAR-IV) approach in Gertler and Karadi (2015). We find that a monetary policy shock resulting in a roughly 0.2*pp* reduction in the 1-year Treasury yield leads to a 1.9*pp* increase in the real S&P 500 return. Using a Campbell and Shiller (1988) decomposition and accounting for estimation uncertainty, 20% – 100% of this increase is driven by lower future excess returns, challenging existing New Keynesian frameworks where essentially all of the

effect on the stock market operates through higher dividends or lower risk-free rates.

Extending the model to the infinite horizon, we investigate whether a calibration to the U.S. economy is capable of rationalizing these facts. We match the heterogeneity in wealth, labor income, and financial portfolios in the Survey of Consumer Finances, together disciplining the exposures to a monetary policy shock and MPRs. We use global solution methods to solve the model. To make the computational burden tractable, we model three groups of households: two groups corresponding to the small fraction with high wealth relative to labor income, but differing in their risk tolerance and thus portfolio share in capital, and one group corresponding to the large fraction holding little wealth relative to labor income. In the data, the high-wealth, high-leverage households are disproportionately those with private business wealth, while the high-wealth, low-leverage households are disproportionately retirees.

We find that the redistribution across households with heterogeneous MPRs can quantitatively explain the risk premium effects of an expansionary monetary policy shock. Notably, the redistribution relevant for this result is between wealthy households holding heterogeneous portfolios, rather than between the asset-poor and asset-rich. Using the same Campbell-Shiller decomposition as was used on the data, over 30% of the return on equity in our baseline parameterization arises from news about lower future excess returns, compared to 0% in a representative agent counterfactual. Consistent with the analytical results, the redistribution to high-MPR households is amplified with a more persistent shock and thus larger debt deflation; higher stickiness and thus a larger increase in profit income relative to labor income; or higher investment adjustment costs and thus a larger increase in the price of capital.

Further consistent with the analytical results, the reduction in the risk premium through redistribution in turn amplifies the effect of policy on the real economy. In both our baseline and counterfactual representative agent economies, we study monetary policy shocks which deliver a 0.2*pp* decline in the 1-year nominal yield on impact. Our model amplifies the response of quantities by 1.3-1.4 times: the peak investment, consumption, and output responses are 2.0*pp*, 0.4*pp*, and 0.7*pp*, while the counterparts in the representative agent economy are 1.6*pp*, 0.3*pp*, and 0.5*pp*.

Related literature Our paper contributes to the rapidly growing literature on heterogeneous agent New Keynesian (HANK) models by studying the transmission of monetary policy through risk premia. We build on Doepke and Schneider (2006) in our

measurement of household portfolios, informing the heterogeneity in exposures to a monetary policy shock. The redistributive effects of monetary policy in our framework follow Auclert (2019). We demonstrate that it is the covariance of these exposures with MPRs rather than MPCs which matters for policy transmission through risk premia. Like Kaplan, Moll, and Violante (2018) and Luetticke (2021), we study an environment with bonds and capital. And like Alves, Kaplan, Moll, and Violante (2020), Auclert, Rognlie, and Straub (2020), and Melcangi and Sterk (2020) we study the effects of monetary policy shocks on asset prices. Unlike these models, in our framework assets differ in exposure to aggregate risk rather than in liquidity, allowing us to account for the important role of risk premia in driving the change in asset prices.

In doing so, we bring to the HANK literature many established insights from heterogeneous agent and intermediary-based asset pricing. The wealth distribution is a crucial determinant of the market price of risk as in other models with heterogeneous risk aversion (e.g., Garleanu and Panageas (2015)), segmented markets (e.g., He and Krishnamurthy (2013)), rules-of-thumb (e.g., Chien, Cole, and Lustig (2012)), background risk (e.g., Constantinides and Duffie (1996)), or heterogeneous beliefs (e.g., Geanakoplos (2009)).² We build on this literature by focusing on the changes in wealth induced by a monetary policy shock in a production economy with nominal rigidities. In studying this question we follow Alvarez, Atkeson, and Kehoe (2009) and Drechsler, Savov, and Schnabl (2018), who study the effects of monetary policy on risk premia in an exchange economy with segmented markets and in a model of banking, respectively.³ We instead study these effects operating through the revaluation of heterogeneous agents' balance sheets in a conventional New Keynesian setting.

Indeed, our paper most directly builds on prior work focused on risk premia in New Keynesian economies. We clarify the sense in which Bernanke, Gertler, and Gilchrist (1999) served as a seminal HANK model focused on heterogeneity in MPRs rather than MPCs.⁴ As we demonstrate, however, heterogeneity in MPRs need not rely on market segmentation, justifying its relevance even in markets which may not be intermediated by specialists. In relating movements in the risk premium to the

²In recent work, Panageas (2020) studies the common implications of these models, and Toda and Walsh (2020) emphasize the role of portfolio heterogeneity in redistribution, as in our analysis.

³More recently, Bhandari, Evans, and Golosov (2019), Chen and Phelan (2021), and Coimbra and Rey (2021) study monetary policy and risk premia in models with segmentation and intermediation.

⁴In Bernanke et al. (1999), households can only trade bonds while entrepreneurs can trade bonds and capital. In equilibrium, households have a zero MPR while entrepreneurs have a positive MPR. Changes in net worth across these agents thus affects credit spreads and economic activity.

real economy, we make use of the insight in Ilut and Schneider (2014), Caballero and Farhi (2018), and Caballero and Simsek (2020) that an increase in the risk premium will induce a recession if the safe interest rate does not sufficiently fall in response.⁵ We build especially on the latter two papers, as well as Brunnermeier and Sannikov (2012, 2016), in emphasizing the effects of heterogeneity in asset valuations on risk premia. Relative to these papers, we explore the importance of such heterogeneity for monetary transmission in a calibration to the U.S. economy.⁶

Like all of these papers, our analysis also provides a theoretical counterpart to the large empirical literature studying links between risky asset prices and real activity. Focusing first on stock prices, the evidence in support of the q -theory of investment has been mixed, and causal estimates of stock prices on consumption are complicated by the fact that they may simply be forecasting other determinants of consumption. Recently, Pflueger, Siriwardane, and Sunderam (2020) and Chodorow-Reich, Nenov, and Simsek (2021) have employed cross-sectional identification strategies to overcome these challenges, finding evidence in support of the cost-of-capital and consumption wealth mechanisms in our model. More broadly interpreting our model as studying the effect of monetary policy on risky claims on capital, there is substantial evidence that spreads on risky corporate debt predict real activity (e.g., Gilchrist and Zakrajsek (2012) and Lopez-Salido, Stein, and Zakrajsek (2017)).

Outline In section 2 we characterize our main insights in a two-period environment. In section 3 we compare empirical evidence on the equity market response to monetary policy shocks to the quantitative predictions of our model enriched to the infinite horizon and calibrated to the U.S. economy. Finally, in section 4 we conclude.

2 Analytical insights in a two-period environment

We first characterize our main conceptual insights in a two-period environment allowing us to obtain simple analytical results. Heterogeneity in risk aversion induces heterogeneity in household portfolios. An expansionary monetary policy shock lowers

⁵While these authors make this point in the case of a time-varying price of risk (as in our model), a similar result obtains with a time-varying quantity of risk as in Fernandez-Villaverde, Guerron-Quintana, Kuester, and Rubio-Ramirez (2015), Basu and Bundick (2017), and DiTella (2020).

⁶In recent complementary work, Pflueger and Rinaldi (2021) study monetary transmission and risk premia in a representative agent New Keynesian model augmented with consumption habits.

the risk premium on capital by redistributing to relatively risk tolerant households. A reduction in the risk premium amplifies the stimulus to investment, consumption, and output. These results are robust to heterogeneity in rules-of-thumb, portfolio constraints, background risk, or beliefs. More generally, they hold whenever levered households, whose relative wealth rises upon a monetary easing, have high propensities to save in capital relative to bonds — i.e., high MPRs.

2.1 Environment

There are two periods, 0 and 1. To isolate the key mechanisms, we make a number of parametric assumptions which are relaxed later in the paper.

Households A unit measure of households indexed by $i \in [0, 1]$ have Epstein-Zin preferences over consumption in each period $\{c_0^i, c_1^i\}$ and labor supply ℓ_0

$$\log v_0^i = (1 - \beta) \log c_0^i - \bar{\theta} \frac{\ell_0^{1+1/\theta}}{1 + 1/\theta} + \beta \log \left(\mathbb{E}_0 \left[(c_1^i)^{1-\gamma^i} \right] \right)^{\frac{1}{1-\gamma^i}}, \quad (1)$$

with a unitary intertemporal elasticity of substitution, discount factor β , relative risk aversion γ^i , (dis)utility of labor $\bar{\theta}$, and Frisch elasticity θ . Labor in period 0 is not indexed by i because (as we describe below) households supply the same amount. In period 1 production only uses capital and thus there is no labor supplied.

In addition to consuming and supplying labor, the household chooses its position in a nominal bond B_0^i and in capital k_0^i subject to the resource constraints

$$P_0 c_0^i + B_0^i + Q_0 k_0^i \leq W_0 \ell_0 + (1 + i_{-1}) B_{-1}^i + (\Pi_0 + (1 - \delta_0) Q_0) k_{-1}^i, \quad (2)$$

$$P_1 c_1^i \leq (1 + i_0) B_0^i + \Pi_1 k_0^i. \quad (3)$$

B_{-1}^i and k_{-1}^i are its endowments in these same assets. The consumption good trades at P_t units of the nominal unit of account (“dollars”) at t ,⁷ the household earns a wage W_0 dollars in period 0, one dollar in bonds purchased at t yields $1 + i_t$ dollars at $t + 1$, and one unit of capital purchased for Q_t dollars at t yields a dividend Π_{t+1} plus $(1 - \delta_{t+1}) Q_{t+1}$ dollars at $t + 1$. Capital fully depreciates after period 1 ($\delta_1 = 1$).

⁷Following Woodford (2003), we model the economy at the cashless limit.

Supply-side The nominal wage is rigid at its level set the previous period

$$W_0 = W_{-1}. \quad (4)$$

Each household is willing to supply the labor demanded of it from firms, appealing to households' market power in the labor market which we spell out later in the paper.

In period 0, the representative producer hires ℓ_0 units of labor and rents k_{-1} units of capital from households to produce the final good with TFP of one. It also uses $\left(\frac{k_0}{k_{-1}}\right)^{\chi^x} x_0$ units of the consumption good to produce x_0 new capital sold to households, where χ^x indexes adjustment costs and it takes k_0 as given. The producer thus earns

$$\Pi_0 k_{-1} = P_0 \ell_0^{1-\alpha} k_{-1}^\alpha - W_0 \ell_0 + Q_0 x_0 - P_0 \left(\frac{k_0}{k_{-1}}\right)^{\chi^x} x_0. \quad (5)$$

In period 1, the producer rents k_0 units of capital and has TFP $\exp(\epsilon_1^z)$, so it earns

$$\Pi_1 k_0 = P_1 \exp(\epsilon_1^z) k_0^\alpha. \quad (6)$$

Future TFP is uncertain in period 0, following

$$\epsilon_1^z \sim N\left(-\frac{1}{2}\sigma^2, \sigma^2\right). \quad (7)$$

Policy The government sets monetary policy $\{i_0, P_1\}$ by committing to $P_1 = P_0$, eliminating inflation risk in the nominal bond,⁸ and following the Taylor rule

$$1 + i_0 = (1 + \bar{i}) \left(\frac{P_0}{P_{-1}}\right)^\phi \exp(\epsilon_0^m) \quad (8)$$

with reference price P_{-1} , where ϵ_0^m is the shock of interest. It follows that the real interest rate between periods 0 and 1 is⁹

$$1 + r_1 \equiv (1 + i_0) \frac{P_0}{P_1} = (1 + \bar{i}) \left(\frac{P_0}{P_{-1}}\right)^\phi \exp(\epsilon_0^m).$$

⁸It is straightforward to allow $P_1 = P_0 \exp(\iota \epsilon_1^z)$ for $\iota \neq 0$, so that there is inflation risk in the nominal bond. Our quantitative analysis in the next section features inflation risk.

⁹Between periods t and $t + 1$ we denote i_t the nominal interest rate known in period t and r_{t+1} the realized real interest rate depending on the price level in period $t + 1$.

Market clearing Market clearing in goods is

$$\int_0^1 c_0^i di + \left(\frac{k_0}{k_{-1}}\right)^{\chi^x} x_0 = \ell_0^{1-\alpha} k_{-1}^\alpha, \quad \int_0^1 c_1^i di = \exp(\epsilon_1^z) k_0^\alpha, \quad (9)$$

in the capital rental market is

$$\int_0^1 k_{-1}^i di = k_{-1}, \quad \int_0^1 k_0^i di = k_0, \quad (10)$$

in the capital claims market is

$$(1 - \delta_0) \int_0^1 k_{-1}^i di + x_0 = \int_0^1 k_0^i di, \quad (11)$$

and in bonds is

$$\int_0^1 B_0^i di = 0. \quad (12)$$

Equilibrium Given the state variables $\{W_{-1}, P_{-1}, \{B_{-1}^i, k_{-1}^i\}, i_{-1}, \epsilon_0^m\}$ and a stochastic process for ϵ_1^z in (7), the definition of equilibrium is then standard:

Definition 1. *An equilibrium is a set of prices and policies such that: (i) each household i chooses $\{c_0^i, B_0^i, k_0^i, c_1^i\}$ to maximize (1) subject to (2)-(3), (ii) wages are rigid as in (4), (iii) the representative producer chooses $\{\ell_0, x_0\}$ to maximize profits (5) and earns profits (6), (iv) the government sets $\{i_0, P_1\}$ according to $P_1 = P_0$ and (8), and (v) the goods, capital, and bond markets clear according to (9)-(12).*

We now characterize the comparative statics of this economy with respect to a monetary policy shock ϵ_0^m in a sequence of three main propositions. Each result builds on the last, and each makes use of only a few equilibrium conditions.

2.2 Monetary policy, redistribution, and the risk premium

We first provide a general result characterizing the effect of a monetary policy shock on the expected excess return on capital.

We need to know each household's desired portfolio in capital. Define i 's real savings

$$a_0^i \equiv b_0^i + q_0 k_0^i,$$

and portfolio share in capital

$$\omega_0^i \equiv \frac{q_0 k_0^i}{a_0^i},$$

where we use lower-case to denote the real analogs to the nominal variables introduced earlier. Let $1 + r_1^k$ denote the gross real returns on capital

$$1 + r_1^k \equiv \frac{\Pi_1 P_0}{Q_0 P_1} = \frac{\pi_1}{q_0}.$$

Then i 's optimality condition for ω_0^i is given by

$$\mathbb{E}_0 \left[(c_1^i)^{-\gamma^i} (r_1^k - r_1) \right] = 0. \quad (13)$$

Taking a Taylor approximation of the expression inside the expectation up to second order in the excess log return, it follows that the optimal portfolio share in capital approximately satisfies

$$\omega_0^i \approx \frac{1}{\gamma^i} \frac{\mathbb{E}_0 \log(1 + r_1^k) - \log(1 + r_1) + \frac{1}{2}\sigma^2}{\sigma^2}. \quad (14)$$

Given a positive risk premium, more risk tolerant households choose a larger portfolio share in capital. This is the only approximation we use in the results which follow.

Simply by aggregating (14) and making use of the asset market clearing conditions (10) and (12), we obtain the first result of the paper, the proof of which (along with all other proofs) is in appendix A:

Proposition 1. *The risk premium on capital is*

$$\mathbb{E}_0 \log(1 + r_1^k) - \log(1 + r_1) + \frac{1}{2}\sigma^2 = \gamma\sigma^2,$$

where

$$\gamma \equiv \left(\int_0^1 \frac{a_0^i}{\int_0^1 a_0^{i'} di'} \frac{1}{\gamma^i} di \right)^{-1}.$$

The change in the risk premium in response to a monetary shock is

$$\frac{d \left[\mathbb{E}_0 \log(1 + r_1^k) - \log(1 + r_1) \right]}{d\epsilon_0^m} = \gamma\sigma^2 \int_0^1 \frac{d \left[a_0^i / \int_0^1 a_0^{i'} di' \right]}{d\epsilon_0^m} (1 - \omega_0^i) di. \quad (15)$$

Hence, a monetary policy shock affects the risk premium if it redistributes across households with heterogeneous desired portfolios. If monetary policy does not redistribute ($d \left[a_0^i / \int_0^1 a_0^{i'} di' \right] / d\epsilon_0^m = 0$ for all i) or households have identical desired portfolios ($\omega_0^i = 1$ for all i), there is no effect on the risk premium. Away from this case, redistributing wealth to households with relatively high desired portfolios in capital lowers the risk premium. Intuitively, such redistribution raises the relative demand for capital, lowering the required excess return to clear asset markets.

2.3 Risk premium and the real economy

We now characterize why a change in the risk premium is relevant for the real economy.

The link between investment and the risk premium is due to the relation between the expected return to capital and investment. Indeed, optimal investment solving (5) and equilibrium dividends in (6) together imply that the expected return on capital is given by

$$\mathbb{E}_0 \log(1 + r_1^k) = \log \alpha + \mathbb{E}_0 \log z_1 + \chi^x \log k_{-1} - (1 - \alpha + \chi^x) \log k_0. \quad (16)$$

Hence, investment is declining in the expected return to capital.

The link between consumption and the risk premium operates through household wealth, both directly through the value of capital holdings and indirectly through the effect of investment on the level of production and thus disposable income. Indeed, household i 's optimal choice of consumption is given by

$$c_0^i = (1 - \beta)n_0^i(w_0\ell_0, P_0, \pi_0, q_0),$$

where we collect i 's wealth as a function of non-predetermined variables in

$$n_0^i(w_0\ell_0, P_0, \pi_0, q_0) \equiv w_0\ell_0 + \frac{1}{P_0}(1 + i_{-1})B_{-1}^i + (\pi_0 + (1 - \delta_0)q_0)k_{-1}^i. \quad (17)$$

Aggregating and making use of firms' resource constraint (5) and the market clearing conditions (9)-(12), we thus obtain:

Proposition 2. *The change in investment in response to a monetary shock is*

$$\frac{dk_0}{d\epsilon_0^m} = -\frac{k_0}{1 - \alpha + \chi^x} \left[\frac{d \left[\mathbb{E}_0 \log(1 + r_1^k) - \log(1 + r_1) \right]}{d\epsilon_0^m} + \frac{d \log(1 + r_1)}{d\epsilon_0^m} \right]. \quad (18)$$

The change in consumption $c_0 \equiv \int_0^1 c_0^i di$ in response to a monetary shock is

$$\frac{dc_0}{d\epsilon_0^m} = \frac{1 - \beta}{\beta} q_0 (1 + \chi^x) \frac{dk_0}{d\epsilon_0^m}.$$

The change in output $y_0 \equiv \ell_0^{1-\alpha} k_{-1}^\alpha$ in response to a monetary shock is

$$\frac{dy_0}{d\epsilon_0^m} = \frac{dc_0}{d\epsilon_0^m} + q_0 \left(1 + \chi^x \frac{x_0}{k_0} \right) \frac{dk_0}{d\epsilon_0^m}. \quad (19)$$

Thus, conditional on the real interest rate, a decline in the risk premium is associated with an increase in investment. The increase in investment stimulates aggregate demand and thus production. Consumption rises both because of the increase in the value of capital holdings and because of the rise in disposable income induced by higher production. This feeds back to further stimulate aggregate demand and thus production.¹⁰ These results apply to the case of a monetary policy shock the broader insights of Caballero and Simsek (2020) linking risk premia and the real economy.

2.4 Monetary transmission via the risk premium

We now sign the transmission of a monetary policy shock via the risk premium.

The relevant measure of redistribution toward household i in Proposition 1 is the change in its savings share. Since agents share the same marginal propensity to save (β), this is equal to the change in its wealth share

$$\frac{d \left[a_0^i / \int_0^1 a_0^{i'} di' \right]}{d\epsilon_0^m} = \frac{d \left[n_0^i / \int_0^1 n_0^{i'} di' \right]}{d\epsilon_0^m}. \quad (20)$$

¹⁰These effects parallel the real effects of a decline in the real interest rate, holding fixed the risk premium. Indeed, as Proposition 2 makes clear, holding fixed the risk premium, a decline in the real interest rate must lead to a fall in the real return on capital as agents rebalance into capital. The associated rise in investment and household wealth stimulates aggregate demand and thus output.

Given (17) and defining $n_0 \equiv \int_0^1 n_0^i di$, the change in its wealth share is in turn

$$\frac{d \left[n_0^i / \int_0^1 n_0^{i'} di' \right]}{d\epsilon_0^m} = \frac{1}{n_0} \left[-\frac{1+i_{-1}}{P_0} B_{-1}^i \frac{d \log P_0}{d\epsilon_0^m} + \left(k_{-1}^i - \frac{n_0^i}{n_0} k_{-1} \right) \left(\frac{d\pi_0}{d\epsilon_0^m} + (1-\delta) \frac{dq_0}{d\epsilon_0^m} \right) \right]. \quad (21)$$

Hence, in this setting there are three channels through which wealth is redistributed on impact of a monetary policy shock: via inflation (which redistributes towards nominal borrowers) or via an increase in profits or the price of capital (which redistribute towards those with a disproportionate claim on capital). These heterogeneous exposures to a monetary shock have been previously explicated in the HANK literature, as by Auclert (2019). Propositions 1 and 2 imply that it is their covariance with desired portfolio shares which matters for transmission through risk premia.

When agents' initial endowments are consistent with their desired portfolios in period 0 — as would be the case in the steady-state of an infinite horizon model — and they start with same initial levels of wealth, we can sharply sign these effects:

Proposition 3. *Suppose agents differ in risk aversion $\{\gamma^i\}$; their initial endowments are consistent with their desired portfolio in period 0 ($\{\omega_{-1}^i = \omega_0^i\}$); and they have the same initial levels of wealth. Then:*

- *a cut in the nominal interest rate lowers the risk premium, and*
- *the resulting stimulus to investment, consumption, and output are larger than a representative agent economy starting from the same aggregate allocation.*

Intuitively, relatively risk tolerant agents finance levered positions in capital by borrowing in nominal bonds.¹¹ A cut in the nominal interest rate generates inflation, an increase in profits, and an increase in the price of capital, redistributing wealth to these agents. Proposition 1 implies that this lowers the risk premium. At least given a conventional Taylor rule, the endogenous response of the real interest rate is not sufficiently strong to overturn the amplification characterized in Proposition 2.

¹¹Recall that leverage here reflects the net economic exposure households have in capital and bonds. In practice, this requires accounting for the balance sheets of firms in which households own equity and the balance sheet of the government, which we do in our quantitative analysis in section 3. For instance, risk tolerant households may simply own equity in firms and risk averse households may simply own nominal claims. The former would be levered through the balance sheets of the firms in which they invest (which must be issuing the nominal claims to the risk averse).

2.5 Other sources of heterogeneity

The preceding results do not rely on heterogeneity in risk aversion alone; they also apply when there is heterogeneity in portfolios arising from other primitives.

Binding constraints or rules-of-thumb Suppose a measure of households are not at an interior optimum in their portfolio choice because of the additional constraint

$$q_0 k_0^i = \omega^i a_0^i,$$

reflecting either a binding leverage constraint or a rule-of-thumb in portfolios. When $\omega^i = 0$ in particular, this means the household cannot participate in the capital market. Such constraints are consistent with prior asset pricing models with segmented markets or rules-of-thumb as well as macro models of the financial accelerator.

Background risk Suppose households are subject to idiosyncratic risk beyond the aggregate risk already described: their capital chosen in period 0 is subject to a shock ϵ_1^i in period 1, modeled as a multiplicative change in the efficiency units of capital. ϵ_1^i is *iid* across households and independent of the aggregate TFP shock ϵ_1^z , and η^i controls the degree of background risk according to

$$\log \epsilon_1^i \sim N \left(-\frac{1}{2} \eta^i \sigma^2, \eta^i \sigma^2 \right).$$

This environment captures features of the large literatures in macroeconomics and finance with entrepreneurial income risk.

Subjective beliefs Suppose household i believes that TFP follows

$$\epsilon_1^z \sim N \left(-\frac{1}{2} \zeta^i \sigma^2, \zeta^i \sigma^2 \right)$$

even though the objective (true) probability distribution remains described by (7). As in the large literature on belief disagreements, households with $\zeta^i > 1$ are “pessimists” and households with $\zeta^i < 1$ are “optimists”.

We can then prove:

Proposition 4. *Suppose households differ in risk aversion $\{\gamma^i\}$, being constrained and (among those that are) constraints $\{\omega^i\}$, background risk $\{\eta^i\}$, and beliefs $\{\zeta^i\}$. Further suppose that their endowments are identical to their choices in period 0 and they are otherwise identical. Then we obtain the same results as in Proposition 3.*

Intuitively, in this more general environment a household's portfolio share in capital is falling in risk aversion γ^i , background risk η^i , and pessimism ζ^i , and rising in the leverage constraint or rule-of-thumb ω^i (if applicable). Regardless of these underlying drivers, so long as households enter period 0 with endowments reflecting these same portfolios, it will be the case that an expansionary monetary policy shock redistributes to those wishing to hold relatively more capital. Thus, an expansionary shock lowers the risk premium, amplifying the stimulus to the real economy.

2.6 Exposures and the marginal propensity to take risk

The robustness of these results derives from the tight link between households' exposures to a monetary policy shock and their marginal portfolio choices given a dollar of income. In a more general environment, we now demonstrate that it is the covariance between the two which governs the effects of such a shock on the risk premium.

Consider how a household's optimal portfolio changes with an additional dollar of income. Let the capital, bond, and total savings policy functions solving each household's micro-level optimization problem be given by $k_0^i(\cdot)$, $b_0^i(\cdot)$, and $a_0^i(\cdot)$, respectively. Their arguments are the household's wealth n_0^i and all other aggregates which the household takes as given, such as the real interest rate r_1 and price of capital q_0 . Then:

Definition 2. *Household i 's marginal propensity to take risk (MPR) is*

$$mpr_0^i \equiv \frac{q_0 \partial k_0^i / \partial n_0^i}{\partial a_0^i / \partial n_0^i}.$$

The MPR summarizes the household's marginal portfolio choice in capital. It captures a dimension of behavior in principle orthogonal to the marginal propensity to consume emphasized in prior work. Note that the following results also hold when inflation risk renders the nominal bond risky; we give the MPR its name because under any realistic calibration the payoff on capital is more risky than on bonds.

In the environment studied in the prior subsections, households' marginal and equilibrium portfolios are identical ($mpr_0^i = \omega_0^i$). This is no longer the case if households have a non-unitary elasticity of intertemporal substitution or supply labor in period 1.¹² We can still obtain analytical results in this more general environment, however, by studying the limit as aggregate risk falls to zero. In doing so, we apply techniques developed by Devereux and Sutherland (2011) in the context of open-economy macroeconomics to the present environment and our particular statistics of interest.¹³ Letting variables with bars denote values at the point of approximation without aggregate risk, and returning to the case without portfolio constraints, rules-of-thumb, background risk, and belief differences for simplicity, we obtain:

Proposition 5. *At the limit of zero aggregate risk, i 's portfolio share in capital is*

$$\bar{\omega}_0^i \equiv \frac{\bar{q}_0 \bar{k}_0^i}{\bar{a}_0^i} = \left(\frac{\bar{c}_1^i}{(1 + \bar{r}_1) \bar{a}_0^i} \right) \frac{\bar{\gamma}}{\gamma^i} - \frac{\bar{w}_1}{(1 + \bar{r}_1) \bar{a}_0^i}, \quad (22)$$

and its MPR is

$$\overline{mpr}_0^i = \frac{\bar{\gamma}}{\gamma^i}, \quad (23)$$

where

$$\bar{\gamma} = \left[\int_0^1 \frac{\bar{c}_1^i}{\int_0^1 \bar{c}_1^{i'} di'} \frac{1}{\gamma^i} di \right]^{-1}. \quad (24)$$

is the harmonic average of risk aversion weighted by households' future consumption.

This proposition naturally generalizes (14). It remains that a household's portfolio share in capital and its MPR are higher the less risk averse it is relative to other households in the economy.¹⁴ Nonetheless, the portfolio share and MPR are no longer the same: a household's portfolio share in capital depends not only on risk aversion but also its motive to hedge labor income also subject to TFP shocks, captured by the last term in (22). This hedging motive is irrelevant on the margin.

¹²The results which follow assume that households supply an identical (unitary) amount of labor in period 1, but this is easily generalized.

¹³In particular, a second-order approximation to optimal portfolio choice and the method of undetermined coefficients implies households' limiting portfolios. A similar approach to the partial derivatives of households' first-order conditions with respect to n_0^i implies their limiting MPRs.

¹⁴Even though we are asking how the individual household allocates wealth both in equilibrium and when given a marginal dollar, the risk aversion of all other households is relevant because this controls the prices faced by the household in general equilibrium.

The distinction between portfolios and MPRs is useful in clarifying their roles in a generalization of Proposition 1, our final analytical result of the paper. Approximating households’ optimal portfolio choice (13) and the asset market clearing conditions (10) and (12) around the point with zero aggregate risk, and denoting with hats log/level deviations from this point, we obtain:

Proposition 6. *Up to third order in the perturbation parameters $\{\sigma, \hat{\epsilon}_1^z, \hat{\epsilon}_0^m\}$,*

$$\mathbb{E}_0 \hat{r}_1^k - \hat{r}_1 + \frac{1}{2} \sigma^2 = \bar{\gamma} \sigma^2 + \left[\bar{\gamma} \int_0^1 \frac{d \left[c_1^i / \int_0^1 c_1^{i'} di' \right]}{d \epsilon_0^m} (1 - \overline{mpr}_0^i) di \right] \hat{\epsilon}_0^m \sigma^2. \quad (25)$$

Hence, a monetary policy shock will lower the risk premium if it redistributes wealth to households with relatively high MPRs. This decouples and clarifies the respective role of portfolios and MPRs. Portfolios — more precisely, those which households enter the period with — govern how wealth redistributes on impact of a monetary policy shock, and are contained in $\frac{d[c_1^i / \int_0^1 c_1^{i'} di']}{d \epsilon_0^m}$. MPRs govern how agents allocate the change in wealth on the margin. We will thus focus on heterogeneity in both portfolios and MPRs in our quantitative results, to which we now turn.

3 Quantitative relevance in the infinite horizon

We first revisit the empirical evidence on the equity premium response to monetary policy shocks which poses a challenge to workhorse models where risk premia barely move. We then calibrate our model to match standard “macro” moments as well as novel “micro” moments from the Survey of Consumer Finances which discipline the cross-sectional heterogeneity in MPRs and exposures to monetary policy. In response to an unexpected monetary easing in our model economy, wealth endogenously redistributes to relatively high MPR households, rationalizing the equity premium response found in the data and amplifying the stimulus in real activity.

3.1 Empirical effects of monetary policy shocks in U.S. data

The effects of an unexpected shock to monetary policy have been the subject of a large literature in empirical macroeconomics. In response to an unexpected loosening, the

price level rises and production expands, consistent with workhorse New Keynesian models. But, as found in Bernanke and Kuttner (2005) and a number of subsequent papers using asset pricing data, the evidence further suggests that risk premia fall.^{15,16}

We refresh the findings in Bernanke and Kuttner (2005) using the structural vector autoregression instrumental variables (SVAR-IV) approach in Gertler and Karadi (2015). Using monthly data from July 1979 through June 2012, we first run a six-variable, six-lag VAR using the 1-year Treasury yield, CPI, industrial production, S&P 500 return relative to the 1-month T-bill, 1-month T-bill return relative to the change in CPI, and smoothed dividend-price ratio on the S&P 500.^{17,18} Over January 1991 through June 2012 we then instrument the residuals in the 1-year Treasury yield (the *monetary policy indicator*) with an external instrument: policy surprises constructed using the current Fed Funds futures contract on FOMC days aggregated to the month level from Gertler and Karadi (2015). The identification assumptions are that the exogenous variation in the monetary policy indicator in the VAR are due to the structural monetary shock and that the instrument is correlated with this structural shock but not the five others. With a first-stage F statistic of 14.4, this instrument is strong according to the threshold of Stock, Wright, and Yogo (2002).

We then plot the impulse responses to a negative monetary policy shock using this instrument in Figure 1. Since the structural monetary policy shock is not observed, its magnitude should be interpreted through the lens of the approximately 0.2*pp* decrease in the 1-year yield on impact. Consistent with the wider literature, industrial production and the price level rise, and the real interest rate falls. Excess returns rise by 1.9*pp* on impact; given the comparatively tiny decline in the real interest rate, this means the real return on the stock market is also approximately 1.9*pp*. Notably, excess returns are small and negative in the months which follow, consistent with a

¹⁵This effect on risk premia may co-exist with the revelation of information, a channel studied by Nakamura and Steinsson (2018) and others. The analysis of Jarocinski and Karadi (2020) implies that by confounding “pure” monetary policy shocks with such information shocks, our estimates may understate the increase in the stock market following a pure monetary easing.

¹⁶In addition to this literature, there is also evidence that changes in the monetary policy rule affect risk premia. For instance, using a regime-switching model Bianchi, Lettau, and Ludvigson (2022) find that a more dovish monetary policy rule is associated with a lower equity premium.

¹⁷The series for the 1-year Treasury yield, CPI, and industrial production are taken from the dataset provided by Gertler and Karadi (2015). The remaining series are from CRSP.

¹⁸The smoothed dividend-price ratio is the 3-month moving average of dividends divided by the price of the stock at the end of the month, value-weighted over the S&P 500. We linearly detrend this series given changes in corporate payout policy over the sample period.

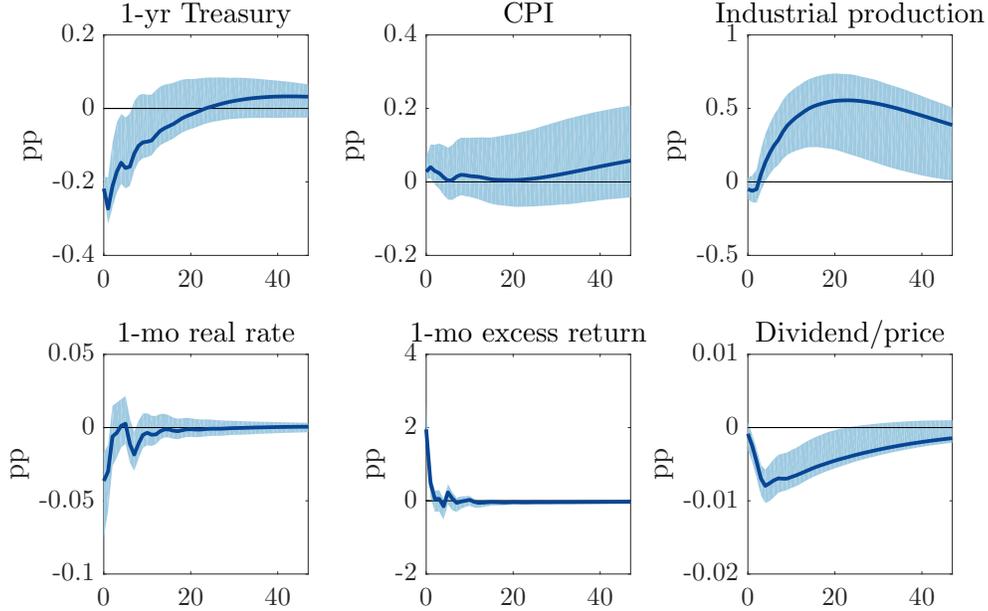

Figure 1: effects of 1 SD monetary shock

Notes: 90% confidence interval at each horizon is computed using the wild bootstrap with 10,000 iterations, following Mertens and Ravn (2013) and Gertler and Karadi (2015).

decline in the equity premium and the fall in the dividend/price ratio.

Following Bernanke and Kuttner (2005), we can decompose the 1.9pp real return on the stock market into news about higher dividend growth, lower real risk-free discount rates, and lower future excess returns using a Campbell-Shiller decomposition:

$$\begin{aligned}
 (\text{real stock return})_t - \mathbb{E}_{t-1}[(\text{real stock return})_t] &= (\mathbb{E}_t - \mathbb{E}_{t-1}) \sum_{j=0}^{\infty} \kappa^j \Delta(\text{dividends})_{t+j} \\
 &- (\mathbb{E}_t - \mathbb{E}_{t-1}) \sum_{j=1}^{\infty} \kappa^j (\text{real rate})_{t+j} - (\mathbb{E}_t - \mathbb{E}_{t-1}) \sum_{j=1}^{\infty} \kappa^j (\text{excess return})_{t+j}, \quad (26)
 \end{aligned}$$

where $\kappa = \frac{1}{1+\frac{d}{p}}$ and $\frac{d}{p}$ is the steady-state dividend yield. Using the SVAR-IV to compute the revised expectations in real rates and excess returns given the monetary shock, we obtain the decomposition in Table I.¹⁹ 1.1pp (59%) of the initial return on the stock market is due to news about lower future excess returns, 0.1pp (8%) is due to news about lower future risk-free rates, and 0.6pp (33%) is due to news about

¹⁹As in Bernanke and Kuttner (2005), we use our VAR to compute $(\text{excess return})_t - \mathbb{E}_{t-1}[(\text{excess return})_t]$, $(\mathbb{E}_t - \mathbb{E}_{t-1}) \sum_{j=1}^{\infty} \kappa^j (\text{real rate})_{t+j}$, and $(\mathbb{E}_t - \mathbb{E}_{t-1}) \sum_{j=1}^{\infty} \kappa^j (\text{excess return})_{t+j}$, and we assign to dividend growth the residual implied by (26).

	<i>pp</i>	As share of effect on real stock return
Real stock return	1.92 [1.54,2.59]	
Dividend growth news	0.64 [-0.25, 1.48]	33% [-13%,71%]
– Future real rate news	0.15 [-0.12,0.39]	8% [-6%,21%]
– Future excess return news	1.13 [0.37,2.27]	59% [19%,108%]

Table I: Campbell-Shiller decomposition following 1 SD monetary shock

Notes: decomposition in (26) uses $\kappa = 0.9962$ following Campbell and Ammer (1993). 90% confidence interval in brackets is computed using the wild bootstrap with 10,000 iterations, following Mertens and Ravn (2013) and Gertler and Karadi (2015).

higher dividend growth. Accounting for estimation uncertainty, at least 19% and potentially all of the return on the stock market is due to news about lower future excess returns, validating the original message from Bernanke and Kuttner (2005).

The important role of the risk premium in explaining the return on the stock market is robust to details of the estimation approach. In appendix B.1 we change the number of lags used in the VAR; change the sample periods over which the VAR and/or first-stage is estimated; add variables to the VAR; and use an alternative instrument for the monetary policy shock. Across these cases we confirm the message of the baseline estimates above: in response to a monetary policy shock which reduces the 1-year Treasury yield by approximately 0.2*pp*, real stock returns rise by 1.5-3.1*pp*, and news about future excess returns explains 35%-85% of this increase.

The dimensionality reduction offered by a VAR enables us to generate the long-horizon forecasts needed for the Campbell-Shiller decomposition, unlike a local projection. As noted by Stock and Watson (2018), we can test the assumption of invertibility implicit in the SVAR-IV both by assessing whether lagged values of the instrument have forecasting power when included in the VAR and by comparing the estimated impulse responses to those obtained using a local projection with instrumental variables (LP-IV). We show in appendix B.1 that both of these tests fail to reject the null hypothesis that invertibility in our application is satisfied.²⁰

²⁰As an alternative approach, a recursive VAR ordering the IV first in the VAR is robust to

Finally, augmenting our VAR with cross-sectional data corroborates the redistributive mechanism through which our model rationalizes the risk premium response to a monetary shock. In appendix B.1, we construct two measures of the relative wealth of agents relatively more exposed to the stock market: a total return index of high beta hedge funds relative to low beta hedge funds, and an analogous index for mutual funds. These measure the relative wealth of a household continually (re-)invested in high beta funds relative to low beta funds. On impact of a monetary easing, we find that the relative return of high beta funds rises on impact and then falls thereafter. This is consistent with the wealth share of relatively risk tolerant investors rising, since risk sharing calls for the wealth of risk tolerant investors to load more on the return on capital — i.e., to have a higher beta.

Objectives in the remainder of paper The rest of the paper enriches the model from section 2 and studies a calibration to the U.S. economy matching micro evidence on portfolio heterogeneity and conventional macro moments on asset prices and business cycles. We first ask whether redistribution in such an environment can quantitatively rationalize the estimated stock market response to a monetary policy shock. We then use the model to quantify the implications for the real economy.

3.2 Infinite horizon environment

We first outline the environment, building on that from section 2.1. We describe the main changes here and present the complete environment in appendix C.

3.2.1 Household preferences and constraints

To ensure a stationary wealth distribution despite permanent differences in risk aversion, we assume a perpetual youth structure in which each household dies at rate ξ and has no bequest motive. This implies an underlying wealth distribution *among* households having a particular coefficient of relative risk aversion γ^i . Appendix C

non-invertibility (Plagborg-Moller and Wolf (2021)), while estimation using a VAR still means that we can implement (26). While the impulse responses using this approach are noisier than our baseline using the SVAR-IV, the point estimates imply that 74% of the increase in the stock market following a monetary shock is due to news about lower future excess returns. The recursive approach is closely related to the identification strategy used by Paul (2020) in recent work also finding that expansionary monetary policy raises the stock market in part by lowering future excess returns.

proves the existence of a representative household at each γ^i .²¹

Representative household i maximizes a generalization of (1)

$$v_t^i = \left((1 - \beta) \left(c_t^i \Phi \left(\int_0^1 \ell_t^i(j) dj \right) \right)^{1-1/\psi} + \beta \mathbb{E}_t \left[(\mu_{t,t+1}^i v_{t+1}^i)^{1-\gamma^i} \right]^{\frac{1-1/\psi}{1-\gamma^i}} \right)^{\frac{1}{1-1/\psi}} \quad (27)$$

with disutility of labor each period

$$\Phi(\ell_t^i) = \left(1 + (1/\psi - 1) \bar{\theta} \frac{(\ell_t^i)^{1+1/\theta}}{1 + 1/\theta} \right)^{\frac{1/\psi}{1-1/\psi}}, \quad (28)$$

consistent with balanced growth as in Shimer (2010) and Trabandt and Uhlig (2011). $\mu_{t,t+1}^i$ reflects the wealth of households of type i at $t + 1$ who were also alive at t , relative to the average household of type i at $t + 1$. It is characterized in appendix C.

We assume each household is comprised of a measure one of workers j supplying a different variety, allowing us to accommodate wage stickiness in the usual way. In particular, each household pays Rotemberg (1982) wage adjustment costs for each j

$$AC_t^W(j) = \frac{\chi^W}{2} W_t \ell_t \left(\frac{W_t(j)}{W_{t-1}(j) \exp(\varphi_t)} - 1 \right)^2, \quad (29)$$

where χ^W controls the magnitude of adjustment costs, $W_t \ell_t$ is the economy-wide wage bill, and $\exp(\varphi_t)$ in the reference wage is an adjustment for rare disasters described below. These adjustment costs are not indexed by i because there is a common wage for each variety supplied by households, as described below. We further assume these costs are paid to the government and rebated back to households so that they only affect the allocation via the dynamics of wages.

Finally, we assume households also face a lower bound on capital

$$k_t^i \geq \underline{k} z_t, \quad (30)$$

where z_t is productivity, discussed below. Such a constraint captures components of capital which households hold for reasons beyond financial returns, such as housing.

²¹So that the model permits aggregation into representative households despite the existence of non-traded labor income, we allow households to trade claims to a labor endowment with other households having the same risk aversion, as further described in appendix C. This approach extends that in Lenel (2020) to a setting with endogenous labor supply and production.

3.2.2 Supply-side

A union representing each variety j chooses $W_t(j)$ and $\ell_t(j)$ to maximize the utilitarian social welfare of union members given the allocation rule

$$\ell_t^i(j) = \phi^i \ell_t(j), \quad (31)$$

satisfying $\int_0^1 \phi^i di = 1$. A representative labor packer purchases varieties and combines them to produce a CES aggregate with elasticity of substitution ϵ

$$\ell_t = \left[\int_0^1 \ell_t(j)^{(\epsilon-1)/\epsilon} \right]^{\epsilon/(\epsilon-1)} \quad (32)$$

which it then sells at W_t , earning

$$W_t \ell_t - \int_0^1 W_t(j) \ell_t(j) dj. \quad (33)$$

A representative producer then purchases the labor aggregate and rents capital, and it uses consumption goods to produce new capital goods sold to households.

3.2.3 Aggregate productivity

We now assume that productivity z_t follows a unit root process

$$\log z_t = \log z_{t-1} + \epsilon_t^z + \varphi_t, \quad (34)$$

where ϵ_t^z is an *iid* shock from a Normal distribution with mean zero and standard deviation σ^z , φ_t is a rare disaster equal to zero with probability $1 - p_t$ and $\underline{\varphi} < 0$ with probability p_t , and p_t follows an AR(1) process

$$\log p_t - \log \bar{p} = \rho^p (\log p_{t-1} - \log \bar{p}) + \epsilon_t^p, \quad (35)$$

where ϵ_t^p is an *iid* shock from a Normal distribution with mean zero and standard deviation σ^p . Following Barro (2006), Gourio (2012), and Wachter (2013), we introduce the disaster with time-varying probability to help match the level of the equity

premium and volatility of returns.²² So that the dynamics upon a rare disaster are well-behaved, we assume that the disaster destroys capital and reduces the reference wage in households' wage adjustment costs in proportion to the decline in productivity. The first assumption implies that aggregate output is

$$y_t \equiv (z_t \ell_t)^{1-\alpha} (k_{t-1} \exp(\varphi_t))^\alpha, \quad (36)$$

where productivity is now labor-augmenting and thus consistent with balanced growth.

3.2.4 Monetary and fiscal policy

Finally, monetary policy is now characterized by the Taylor rule (8) each period

$$1 + i_t = (1 + \bar{i}) \left(\frac{P_t}{P_{t-1}} \right)^\phi m_t, \quad (37)$$

where policy shocks follow an AR(1) process

$$\log m_t = \rho^m \log m_{t-1} + \epsilon_t^m, \quad (38)$$

where ϵ_t^m is an *iid* shock from a Normal distribution with mean zero and standard deviation σ^m .

Fiscal policy is characterized by three elements. First, the government subsidizes workers' labor income at a constant rate $\frac{1}{\epsilon-1}$ rebated back to each household, eliminating the average wage markup in the usual way. Second, the government participates in the bond market financed by lump-sum taxes in which household i pays a share ν^i . Given the latter assumption (and that households face no constraints in the bond market) the government bond position has no effect on the equilibrium allocation, so we assume it is a constant real value relative to productivity: $B_t^g/(P_t z_t) = b^g$. Its only purpose is to make measured portfolios in model and data comparable. Third, the government collects the wealth of dying households and endows it to newborn households. We describe the rule employed when doing so in the next subsection.

²²Following Bianchi, Ilut, and Schneider (2018), financial frictions on firms together with uncertainty shocks on operating cost could further improve the model on this dimension. Following Guvenen (2009) and Garleanu and Panageas (2015), heterogeneity in the intertemporal elasticity of substitution could also help lower the volatility of the real interest rate relative to excess returns.

3.2.5 Equilibrium and model solution

The definition of equilibrium naturally generalizes Definition 1.

We solve the model globally using numerical methods. Given this, we limit the heterogeneity across households to make the computation tractable. We divide the continuum of households into three groups $\{a, b, c\}$ within which households have identical preferences. The index i now refers to the representative household of each group. The fraction of households belonging to group i is denoted λ^i , where $\sum_i \lambda^i = 1$.

We solve a stationary transformation of the economy obtained by dividing all real variables except labor by z_t and nominal variables by $P_t z_t$. In the transformed economy we obtain a recursive representation of the equilibrium in which the aggregate state in period t is given by the monetary policy state variable m_t , disaster probability p_t , scaled aggregate capital $k_{t-1}/(z_{t-1} \exp(\epsilon_t^z))$, scaled prior period's real wage $w_{t-1}/(z_{t-1} \exp(\epsilon_t^z))$, and wealth shares $\{s_t^i\}$ of any two groups. Assuming that the government endows newborn households of each group with a share \bar{s}^i of dying households' wealth, these wealth shares follow

$$s_t^i \equiv \lambda^i (1 - \xi) \frac{(1 + i_{t-1})(B_{t-1}^i + \nu^i B_{t-1}^g) + (\Pi_t + (1 - \delta)Q_t)k_{t-1}^i \exp(\varphi_t)}{(\Pi_t + (1 - \delta)Q_t)k_{t-1} \exp(\varphi_t)} + \xi \bar{s}^i. \quad (39)$$

Productivity shocks inclusive of disasters only govern the transition across states, but do not separately enter the state space itself.

We solve the model using sparse grids as described in Judd, Maliar, Maliar, and Valero (2014). When forming expectations, we use Gauss-Hermite quadrature and interpolate with Chebyshev polynomials for states off the grid. The stochastic equilibrium is determined through backward iteration, while dampening the updating of asset prices and individuals' expectations over the dynamics of the aggregate states. The code is written in Fortran and parallelized using OpenMP, so that convergence can be achieved in a few minutes on a standard desktop computer.

3.3 Parameterization, first moments, and second moments

We now parameterize the model to match micro moments informing the heterogeneity across groups as well as macro moments regarding the business cycle and asset prices.

3.3.1 Micro: the distribution of wealth, labor income, and portfolios

We seek to match the distribution of wealth, labor income, and financial portfolios in U.S. data, giving us confidence in the model’s MPRs and exposures to a monetary shock. We proceed in three steps with the 2016 Survey of Consumer Finances (SCF).

First, we decompose each household’s wealth (A^i) into claims on the economy’s capital stock (Qk^i , in positive net supply) and nominal claims (B^i , in zero net supply accounting for the government and rest of the world). We describe this procedure in detail in appendix B.2 and provide a broad overview here. We first add estimates of defined benefit pension wealth for each household since this is the major component of household net worth which is excluded from the SCF.²³ We then proceed by line item to allocate how much household wealth is held in nominal claims versus claims on capital.²⁴ In the same spirit as Doepke and Schneider (2006), the key step in doing this is to account for the implicit leverage households have on capital through publicly-traded and privately-held businesses. The aggregate leverage implicit in these equity claims must be consistent with that of the business sectors in the Financial Accounts. We parameterize the dispersion in leverage in these claims to match evidence on the dispersion in households’ expected rates of return.

Second, we stratify households by their wealth to labor income $\{\frac{A^i}{W\ell^i}\}$ and capital portfolio share $\{\frac{Qk^i}{A^i}\}$, defining our three groups. We sort households on these variables based on Proposition 5, which demonstrated that the capital portfolio share is informative about households’ risk aversion and thus MPR only after properly accounting for their non-traded exposure to aggregate risk through labor income.²⁵ Group *a* corresponds to households with high wealth to labor income and a high capital portfolio share, group *b* corresponds to households with high wealth to labor income but a low capital portfolio share, and group *c* corresponds to households with low wealth to labor income. We define “high” wealth to labor income as households

²³We use the estimates of Sabelhaus and Volz (2019) described further in the appendix.

²⁴We note in particular that we treat DB pension entitlements as a nominal asset of households, under the interpretation that households have a fixed claim on the pension sponsor which is then the residual claimant on the investment portfolio. In contrast, DC pension assets, as with other mutual fund assets, are decomposed into nominal claims and claims on capital as described here.

²⁵We sort households by a measure of their capital portfolio share after excluding from both the numerator and denominator assets and liabilities associated with the primary residence and vehicles, even though for each group we report and target the capital portfolio share accounting for all assets and liabilities. We sort households on the former measure since households’ decisions regarding their primary residence and consumer durables may reflect considerations beyond risk and return.

		$\frac{A^i}{W\ell^i}$	
		$\geq p60$	$< p60$
$\frac{Qk^i}{A^i}$	$\geq p90$	Group a Share households: 4% $\sum_{i \in a} W\ell^i / \sum_i W\ell^i$: 3% $\sum_{i \in a} A^i / \sum_i A^i$: 18% $\sum_{i \in a} Qk^i / \sum_{i \in a} A^i$: 2.0	Group c Share households: 60% $\sum_{i \in c} W\ell^i / \sum_i W\ell^i$: 83% $\sum_{i \in c} A^i / \sum_i A^i$: 23% $\sum_{i \in c} Qk^i / \sum_{i \in c} A^i$: 1.1
	$< p90$	Group b Share households: 36% $\sum_{i \in b} W\ell^i / \sum_i W\ell^i$: 14% $\sum_{i \in b} A^i / \sum_i A^i$: 58% $\sum_{i \in b} Qk^i / \sum_{i \in b} A^i$: 0.5	

Table II: heterogeneity in wealth to labor income and the capital portfolio share

Notes: observations are weighted by SCF sample weights.

above the 60th percentile of this measure, and a “high” capital portfolio share as households above the 90th percentile of this measure.²⁶

Third, we summarize the labor income, wealth, and financial portfolios of these three groups, provided in Table II. Group *a* households earn 3% of labor income, hold 18% of wealth, and have an aggregate capital portfolio share of 2.0. Group *b* households earn only 14% of labor income, hold 58% of wealth, and have an aggregate capital portfolio share of 0.5. Group *c* households earn 83% of labor income, hold only 23% of wealth, and have an aggregate capital portfolio share of 1.1. To better understand the nature of households in each group, in Table III we first project an indicator for the household having private business wealth on households’ group indicator. Households in group *a* are especially more likely to have private business wealth. We then project an indicator for the household head being older than 54 and out of the labor force, together capturing a retired household head, on households’ group indicator. Households in group *b* are especially more likely to be retired.

²⁶The 90th percentile strikes a balance between capturing the tail of levered households and maintaining a large enough sample size. In appendix D.2, we consider the robustness of our results to raising this cutoff to the 99th percentile. In this case, *a* households hold less wealth but are much more levered, and in fact have approximately the wealth share and leverage of the broker-dealer and hedge fund sectors, admitting an intermediary asset pricing interpretation to this calibration.

	$1\{hbus^i = 1\}$	$1\{age^i > 54, lf^i = 0\}$
$1\{i \in a\}$	0.37 (0.03)	0.37 (0.03)
$1\{i \in b\}$	0.05 (0.01)	0.55 (0.01)
Observations	6,229	6,229
Adj R^2	0.05	0.37

Table III: indicators for private business wealth or being retired on group indicators

Notes: observations are weighted by SCF sample weights and standard errors adjust for imputation and sampling variability following Pence (2015). Each specification includes a constant term (not shown), capturing the baseline probability of holding private business wealth or being retired among households in group c .

In appendix B.2, we apply the exact same approach as above to stratify households in 2007 using the 2007-2009 SCF panel. We then exploit the panel structure of this survey to follow households through 2009. Among other findings, we document that households' portfolio share in capital are very persistent across these two years, both at the group and individual levels. This validates our calibration approach of matching the cross-sectional data using permanent differences in households' risk preferences.

3.3.2 Macro: business cycle dynamics and asset prices

We also calibrate the model to match standard macro moments regarding the business cycle and asset prices. In terms of the business cycle, we use NIPA data on consumption of non-durables and services as well as investment in durables and capital, together with the time series of the working age population from the BLS, to estimate the volatilities of quarterly per capita growth rates in those series over Q3 1979 to Q2 2012 (consistent with our sample period for the VAR). In terms of asset prices, we use the data from CRSP described earlier to estimate the annualized average real interest rate and excess return on the S&P 500 over July 1979 - June 2012. We further estimate the second moments of expected returns using our VAR. We compute analogous moments in our model assuming that an equity claim (with return r^e) is a levered claim to capital with a debt to equity ratio of 0.5.²⁷

²⁷This ratio is commonly used in the literature (e.g., Barro (2006)). It also implies assets to equity of 1.5, very close to our estimate of 1.6 for public equities in appendix B.2.

3.3.3 Parameterization

A model period corresponds to one quarter. After setting a subset of parameters in accordance with the literature, we calibrate the remaining parameters to be consistent with the macro and micro moments described above. All stochastic properties of the model are estimated using a simulation where no disasters are realized in sample.²⁸

Externally set parameters A subset of model parameters summarized in Table IV are set externally. Among the model’s preference parameters, we set ψ to 0.8. We note that this parameter controls both the intertemporal elasticity of substitution in consumption as well as the complementarity between consumption and labor. A value less than one is consistent with evidence on the consumption responses to changes in interest rates as well as consumption-labor complementarity.²⁹ The Frisch elasticity of labor supply is set to $\theta = 1$, roughly consistent with the micro evidence for aggregate hours surveyed in Chetty, Guren, Manoli, and Weber (2011). The three types have measure $\lambda^a = 4\%$, $\lambda^b = 36\%$, and $\lambda^c = 60\%$ and the labor allocation rule features $\phi^a = 3\%/\lambda^a$, $\phi^b = 14\%/\lambda^b$, and $\phi^c = 83\%/\lambda^c$, consistent with Table II. Households die with probability $\xi = 1\%$, implying an expected horizon of 25 years, consistent with households transitioning across groups through the life cycle.

On the production side, we choose standard values of $\alpha = 0.33$ for the capital share of production and $\delta = 2.5\%$ for the quarterly depreciation rate. We set \bar{p} so that, accounting for Jensen’s inequality and the calibrated volatility and persistence σ^p and ρ^p below, the average disaster probability $p = 0.5\%$. This follows Barro (2006) and implies that a disaster shock is expected to occur every 50 years. The depth of the disaster is set to $\underline{\varphi} = -15\%$, consistent with the estimates of Nakamura, Steinsson, Barro, and Ursua (2013) who account for the recovery after a disaster. We choose an elasticity of substitution across worker varieties $\epsilon = 10$ and Rotemberg wage adjustment costs of $\chi^W = 150$, together implying a Calvo (1983)-equivalent frequency of wage adjustment between 4 and 5 quarters, consistent with the evidence in Grigsby, Hurst, and Yildirmaz (2021).

Finally, in terms of policy, we set the Taylor coefficient on inflation to the standard value $\phi = 1.5$. Monetary policy shocks have a standard deviation of $\sigma^m = 0.25\%/4$ with zero persistence. The share of lump-sum taxes financing government debt paid

²⁸We make this choice since we compare the model to post-World War II data.

²⁹See, for instance, Barsky, Juster, Kimball, and Shapiro (1997), Hall (2009), and Shimer (2010).

	Description	Value	Notes
ψ	IES	0.8	
θ	Frisch elasticity	1	Chetty et al. (2011)
λ^a	measure of a households	4%	population in SCF
λ^b	measure of b households	36%	population in SCF
ϕ^a	labor a households	$3\%/\lambda^a$	labor income in SCF
ϕ^b	labor b households	$14\%/\lambda^b$	labor income in SCF
ξ	death probability	1%	
α	1 - labor share	0.33	
δ	depreciation rate	2.5%	
ϵ	elast. of subs. across workers	10	
χ^W	Rotemberg wage adj costs	150	$\approx \mathbb{P}(\text{adjust}) = 4 - 5$ qtrs
\bar{p}	disaster probability	0.45%	$p = 0.5\%$ (Barro (2006))
$\underline{\varphi}$	disaster shock	-15%	Nakamura et al. (2013)
ϕ	Taylor coeff. on inflation	1.5	Taylor (1993)

$\lambda^c \nu^c$	c share of taxes to finance $-B^g$	23%	wealth in SCF

Table IV: externally set parameters

by group i ($\lambda^i \nu^i$) is equal to their wealth share in Table II.

Calibrated parameters We calibrate the remaining parameters to target the macro and micro moments described above. Table V reports in each line a parameter choice and moment in model and data that this parameter is closely linked to.

We first match the first and second moments of quantities and returns. The standard deviation of the productivity shock σ^z is set to 0.55% to match quarterly consumption growth volatility of 0.5%. The capital adjustment cost is set to $\chi^x = 3.5$ to target the volatility of investment growth. Due to the precautionary savings motive, $\beta = 0.98$ is high enough to match the low annualized real rate observed in the data. We set $\gamma^b = 25.5$ to target the annualized excess return on equity. The standard deviation σ^p and persistence ρ^p in the disaster probability process target the standard deviation and autocorrelation of the annualized expected real rate from our VAR.

	Description	Value	Moment	Target	Model
σ^z	std. dev. prod.	0.55%	$\sigma(\Delta \log c)$	0.5%	0.6%
χ^x	capital adj cost	3.5	$\sigma(\Delta \log x)$	2.1%	2.0%
β	discount factor	0.98	$4r_{+1}$	1.3%	1.5%
γ^b	RRA b	25.5	$4[r_{+1}^e - r_{+1}]$	7.3%	7.0%
σ^p	std. dev. log dis. prob.	0.47	$\sigma(4\mathbb{E}r_{+1})$	2.2%	2.2%
ρ^p	persist. log dis. prob.	0.8	$\rho(4\mathbb{E}r_{+1})$	0.79	0.75
γ^a	RRA a	10	qk^a/a^a	2.0	2.3
\underline{k}	lower bound k^i	10	qk^c/a^c	1.1	0.9
$\xi \bar{s}^a$	newborn endowment a	0%	$\lambda^a a^a / \sum_i \lambda^i a^i$	18%	21%
$\xi \bar{s}^c$	newborn endowment c	-0.25%	$\lambda^c a^c / \sum_i \lambda^i a^i$	23%	23%
b^g	real value govt bonds	-2.7	$-\sum_i \lambda^i b^i / \sum_i \lambda^i a^i$	-10%	-10%

Table V: targeted moments and calibrated parameters

Notes: targeted business cycle moments are from Q3/79-Q2/12 NIPA and targeted asset pricing moments are from 7/79-6/12 data underlying the VAR. The model assumes a debt/equity ratio of 0.5 on a stock market claim. The first and second moments in the model are estimated over 50,000 quarters after a burn-in period of 5,000 quarters, with no disaster realizations in sample. The disutilities of labor $\{\bar{\theta}^a, \bar{\theta}^b, \bar{\theta}^c\}$ are jointly set to $\{0.64, 2.89, 0.43\}$ so that the average labor wedge is zero for each group and $\ell = 1$, where the latter is a convenient normalization. The Taylor rule intercept \bar{i} is set to 0.3% to target zero average inflation.

We next match the micro heterogeneity in portfolios and wealth. We set $\gamma^a = 10 < \gamma^b$ to target a households' capital portfolio share. γ^c and \underline{k} are difficult to separately calibrate: the relatively high ratio of labor income to wealth among group c households means that they would endogenously choose to hedge this exposure to productivity shocks by holding a lower position in capital, consistent with Proposition 5, and are thus more likely to be constrained by (30). We set γ^c equal to the (population-weighted) harmonic mean of γ^a and γ^b and calibrate \underline{k} to target the capital portfolio share of c households in the data.³⁰ The initial endowments of newborns are chosen to target the measured wealth shares of the three groups. Matching these wealth shares requires that only b households receive a positive endowment when born.³¹

³⁰We view this as a realistic description of the data, given that \underline{k} is meant to capture components of the economy's capital stock which households hold for reasons beyond their financial returns. In the SCF, 51% of the aggregate capital held by group c households is in their primary residence and vehicles, while the same ratio is only 35% for group b households and 7% for group a households.

³¹This is consistent with the fact that in the SCF, total federal transfers less taxes (estimated using NBER Taxsim) is higher for b households than a or c households. We note that a negative

Moment (ann.)	Data	Model
$\sigma(\Delta \log y)$	0.8%	0.9%
$\sigma(\Delta \log \ell)$	0.8%	0.8%
$\sigma(d/p)$	0.2%	0.2%
$\sum_i \lambda^i mpr^i$	≈ 0.2	0.3
mpr^a		1.9
mpr^b		0.7
mpr^c		0.0
$\sum_i \lambda^i mpc^i$	≈ 0.2	0.02
mpc^a		0.02
mpc^b		0.02
mpc^c		0.02

Table VI: untargeted macro and micro moments

Notes: see notes accompanying Table V on construction of moments in data and model.

Finally, we set b^g so that the aggregate bond position of households relative to total wealth is 10%, as implied by Table II. We set the disutilities of labor so that the average labor wedge is zero for each group and $\ell = 1$, the latter a convenient normalization. We set the Taylor rule intercept \bar{i} so that average inflation is zero.

3.3.4 Untargeted moments

Table VI reports the values of several untargeted moments and their empirical counterparts. In terms of macro moments, the model closely matches the quarterly volatilities of output growth, employment growth, and the smoothed dividend price ratio.^{32,33} Related to the latter, the model generates a quarterly volatility of annualized expected excess equity returns of 2.8%, which accounts for more than half of the volatility estimated in the data by the studies surveyed in Duarte and Rosa (2015).

Turning to micro moments, we first consider MPRs. The model generates het-

value for \bar{s}^c simply means that newborn c households are taxed out of their initial labor income.

³²When computing the smoothed dividend price ratio, we smooth dividends over 12 months rather than over 3 months as in the VAR. This is meant to more accurately compare our model (which features no dividend adjustment costs) with the data.

³³While we emphasize monetary shocks in the main text given that monetary transmission is our focus in this paper, these shocks contribute little to aggregate fluctuations. Appendix D.1 studies productivity shocks and changes in disaster probabilities, the drivers of fluctuations in our model.

erogeneity in quarterly MPRs consistent with Proposition 5 in the analytical results. Group *a* households are the most risk tolerant and have the highest MPR, borrowing \$0.9 for every \$1 of marginal net worth to invest in capital. Group *b* and *c* households have higher levels of risk aversion and correspondingly lower MPRs. As noted above, group *c* households have a higher ratio of labor income to wealth and thus are endogenously constrained by (30). Hence, on the margin their average MPR is zero.

Quasi-experimental evidence is consistent with the MPRs in our calibration. Weighting by the fraction of households, the average MPR in our model is 0.3. Using data on Norwegian lottery winners, Fagereng, Holm, and Natvik (2021) estimate an average marginal propensity to save in risky assets relative to save overall of 0.14.³⁴ Using data on Swedish lottery winners, Briggs, Cesarini, Lindqvist, and Ostling (2015) estimate an analogous ratio of 0.15.³⁵ These imply an MPR of roughly 0.2 after accounting for reasonable estimates of the leverage of firms in which households invest.³⁶ MPRs further rise with wealth per household in our calibration — recalling that wealth per household is highest among *a* households and then *b* households — consistent with evidence from these studies.³⁷ While the range in estimated MPRs in these studies is smaller than that in our model, estimated MPRs based on lotteries may underestimate the relevant statistic for households in groups *a* and *b* of our model. As lottery winnings are paid out as cash or riskless deposits, the estimated MPR may understate the MPR in response to dividends or capital gains, more relevant for the balance sheet revaluation among the wealthy (*a* and *b* households) emphasized in this paper.³⁸ Among owners of private businesses, overrepresented in these households, the estimated MPR may particularly understate their true MPR because investment in private businesses is not included in the definition of (traded) risky assets.

The model’s heterogeneity in MPRs contrasts with its implied MPCs, which are

³⁴In their Table 6, the average marginal propensity to save in stocks, bonds, and mutual funds is 0.058 and the marginal propensity to save in these assets, deposits, or repay debt is 0.407.

³⁵In their Table B.8, the average marginal propensity to save in risky assets is 0.085 and the marginal propensity to save in these assets, safe assets, bank accounts, or repay debt is 0.58.

³⁶With firm leverage of 1.6 estimated in appendix B.2, these estimates imply an MPR of 0.22-0.24.

³⁷Table 5(B) of Fagereng et al. (2021) demonstrates that the MPR of households in the lowest quartile of wealth is below that of others. Figure 3 of Briggs et al. (2015) demonstrates that the MPR of households in the bottom half of the age-adjusted wealth distribution is below that of others.

³⁸Using the Panel Study of Income Dynamics, Brunnermeier and Nagel (2008) document significant inertia in financial portfolios, with a negative change in the risky share after receiving one dollar of cash or deposits but an increase in the risky share after receiving one dollar of unexpected returns on risky assets. In recent work, Fagereng, Holm, Moll, and Natvik (2019) also find evidence that households “save by holding” on to nearly 100% of assets experiencing capital gains.

essentially identical across agents. This is an intentional implication of our model environment which features no idiosyncratic labor income risk nor heterogeneity in discount factors, allowing us to focus on the consequences of heterogeneity in portfolio choice alone. Unsurprisingly, the model further generates an average quarterly MPC which is an order of magnitude lower than that typically estimated in the data. We expect that adding additional features to our model which raise the average MPC would only amplify the real consequences of movements in the risk premium.³⁹

We finally note that, consistent with our analytical results, it is the exposures and MPRs in our calibration which are essential for the effects of a monetary shock — not the precise microfoundation. In appendix D.3, we consider an alternative environment in which households have identical risk aversion but are exposed to heterogeneous amounts of idiosyncratic risk in their return on capital, as in the environment with background risk described in section 2.5 and the broader literature on entrepreneurship in macroeconomic models. To match the same data on portfolios, a households are calibrated to be exposed to less idiosyncratic risk than other agents; equivalently, their risk-adjusted returns are highest. The resulting MPRs are very similar to the baseline model, and the quantitative results which follow are robust.

3.4 Impulse responses to a monetary policy shock

We now simulate the effects of a negative shock to the nominal interest rate. We demonstrate that our model can rationalize the stock market responses to a monetary policy shock in the data. The effects of monetary policy on the risk premium on capital amplify the transmission to the real economy by 1.3-1.4 times.

3.4.1 Model versus RANK

Figures 2, 3, and 4 compare the impulse responses to those in a counterfactual representative agent New Keynesian (RANK) economy. In the latter, we set $\gamma^i = 19$ for all groups, equal to the wealth-weighted harmonic mean of risk aversion in the model.

We choose the shock ϵ_0^m in our model to generate a 0.2pp reduction in the 1-year nominal yield, consistent with section 3.1. We obtain this yield by computing, in each state, the price that each household would pay for a 1-year nominal bond. We then

³⁹This is suggested by the Keynesian cross in Proposition 2 and recent analyses of investment and asset prices in HANK models such as Auclert et al. (2020) and Caramp and Silva (2021).

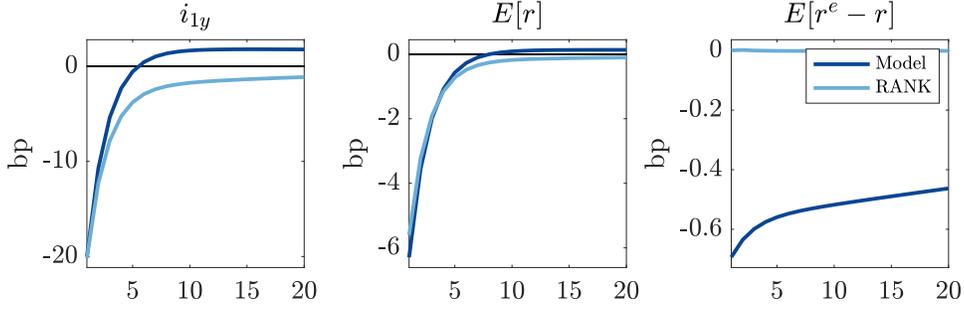

Figure 2: expected returns after negative monetary policy shock

Notes: series are quarterly (non-annualized) measures, except for the 1-year nominal bond yield Δi_{1y} . Impulse responses are the average response (relative to no shock) starting at 1,000 different points drawn from the ergodic distribution of the state space, itself approximated using a sample path over 50,000 quarters after a burn-in period of 5,000 quarters. *bp* denotes basis points (0.01%).

set the price to that of the highest-valuation household. Importantly, we re-calibrate ϵ_0^m in the RANK economy to match this same decline in the 1-year yield.

Figure 2 summarizes the effect of the monetary policy shock on expected returns. The first panel reports the change in the yield on the 1-year nominal bond. The second and third panels depict the resulting change in the expected real interest rate and the expected excess returns on capital. The latter is clear: the risk premium declines substantially and persistently in the model, unlike RANK. The former is more nuanced: the expected real interest rate initially declines by more relative to RANK, but in the subsequent quarters exceeds that in RANK. This is because we need to simulate a more negative ϵ_0^m in the model to match the same decline in the 1-year Treasury, since monetary policy endogenously tightens in subsequent quarters in response to the stimulus from lower risk premia. For this reason, the results which follow are similar if we calibrate the shock in RANK to minimize the absolute value difference between the expected real interest rate path versus the model. Following Proposition 2, we can thus interpret differences in the macro dynamics between the model and RANK as arising from the differing risk premium responses.

Figure 3 demonstrates that redistribution drives the decline in the risk premium in our model. The first panel of the first row demonstrates that realized excess returns on capital are substantially positive on impact, followed by small negative returns in the quarters which follow — consistent with the initial decline in expected excess returns and the empirical pattern estimated in Figure 1. The positive excess return on impact follows from each of the channels characterized in section 2.4: unexpected inflation

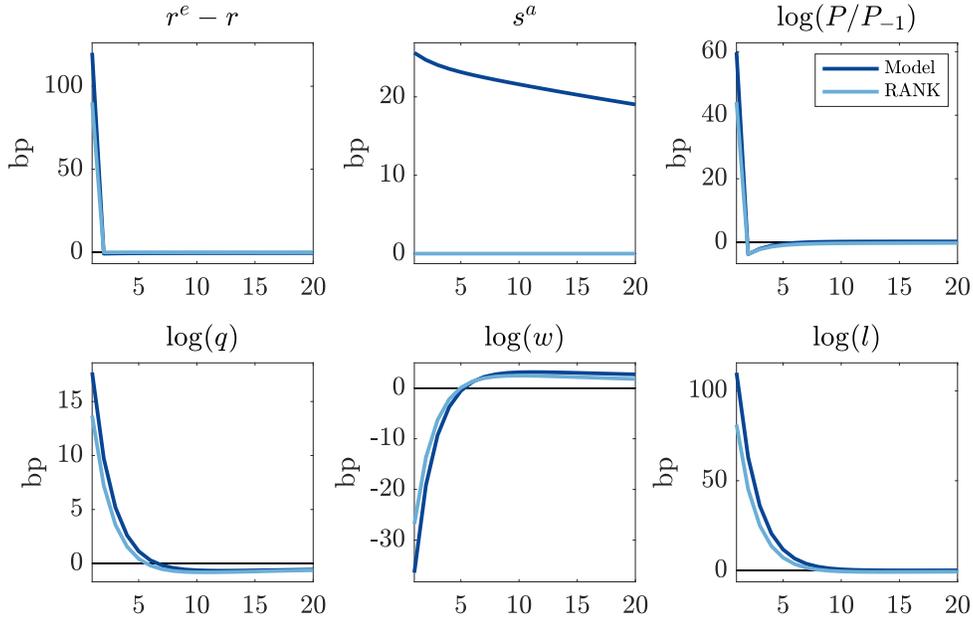

Figure 3: redistribution after negative monetary policy shock

Notes: see notes accompanying Figure 2 on construction of impulse responses.

which lowers the realized real interest rate,⁴⁰ shown in the third panel; a higher price of capital, shown in the first panel of the second row; and higher short-run profits due to lower real wages and higher employment in this sticky wage environment, shown in the second and third panels of this row. Together these forces redistribute to the high MPR a households who hold levered claims on capital, evident from their financial wealth share shown in the second panel of the first row. The persistence in their wealth share drives the persistent decline in expected excess returns.

Figure 4 examines the consequences for policy transmission to the real economy. The impact effects on investment, consumption, and output are 1.3-1.4 times larger versus the RANK economy. Moreover, the stimulus in our model remains persistently higher than the RANK economy despite the endogenous tightening of monetary policy in the model because the risk premium falls by more than the risk-free rate rises. These patterns are consistent with our discussion of Proposition 2.

Quantitatively, the price and quantity effects of the monetary policy shock in

⁴⁰While the response of inflation is more immediate in the model than estimated in the data in Figure 1, in practice much nominal debt has longer duration than the one period assumed in the model. Hence, we conjecture that more sluggish price inflation would not change the redistribution of wealth much if the model was also enriched to feature longer duration nominal debt.

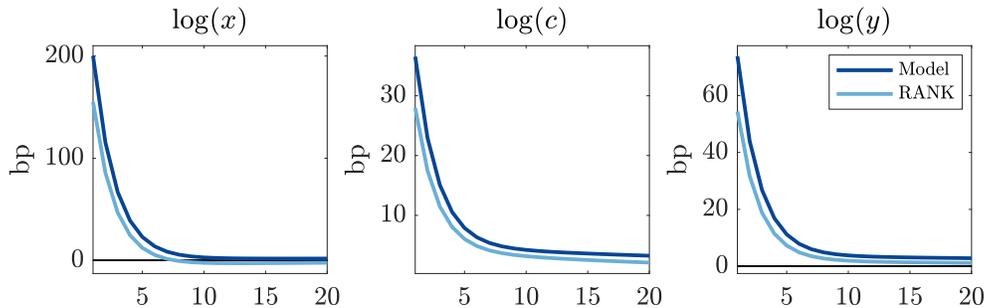

Figure 4: quantities after negative monetary policy shock

Notes: see notes accompanying Figure 2 on construction of impulse responses.

our model are consistent with the empirical estimates even though these were not targeted in the calibration. First, the impact effect on excess returns of $1.2pp$ is only slightly lower than the $1.9pp$ increase estimated in Figure 1. Second and crucially, a Campbell-Shiller decomposition on the model impulse responses matches the role of news about lower future excess returns in driving the initial stock market return in the data. We summarize this in Table VII. The model contrasts starkly with the RANK economy, where essentially none of the transmission to the stock market operates through news about future excess returns. Third, the peak output stimulus in the model of $0.7pp$ is comparable to the peak industrial production stimulus estimated in Figure 1, giving us confidence in the model’s real predictions.⁴¹

3.4.2 Decomposing redistribution and its consequences

We can further use households’ policy functions in capital to decompose the sources of redistribution and its consequences for capital accumulation. As clarified in Proposition 2, it is the amplification in capital accumulation which also underlies the amplification in consumption and thus overall output in our model.

In particular, given the policy function $k^i(n^i, \epsilon^m, \Theta)$ in the recursive representation of the economy in which n^i denotes the agent’s net worth, ϵ^m denotes the value of the monetary shock, and Θ denotes all other pre-determined state variables, we can decompose the elasticity of a household’s capital holdings to a monetary shock into

$$\frac{d \log k^i}{d \epsilon^m} = \left(\frac{n^i}{q k^i} \right) \left(q \frac{\partial k^i}{\partial n^i} \right) \left(\frac{d \log n^i}{d \epsilon^m} \right) + \frac{\partial \log k^i}{\partial \epsilon^m}, \quad (40)$$

⁴¹We conjecture that adding features such as investment adjustment costs could better match the hump-shapes estimated in the data, following Christiano, Eichenbaum, and Evans (2005).

% Real stock return	Data [90% CI]	Model	RANK
Dividend growth news	33% [-13%,71%]	52%	65%
–Future real rate news	8% [-6%,21%]	16%	35%
–Future excess return news	59% [19%,108%]	32%	0%

Table VII: Campbell-Shiller decomposition after monetary shock

Notes: estimates from data correspond to Table I. Comparable estimates obtained in the model assuming a debt/equity ratio of 0.5 on a stock market claim.

where the first term on the right-hand side summarizes the response due to the change in the household’s wealth and the second summarizes the response to the changes in prices and future state variables. The elasticity of the household’s wealth is in turn

$$\frac{d \log n^i}{d\epsilon^m} = \frac{1}{n^i} \frac{dw\ell^i}{d\epsilon^m} - \frac{1+i_{-1}}{P} \frac{B_{-1}^i + \nu^i B_{-1}^g}{n^i} \frac{d \log P}{d\epsilon^m} + \frac{k_{-1}^i}{n^i} \left(\frac{d\pi}{d\epsilon^m} + (1-\delta) \frac{dq}{d\epsilon^m} \right) + \frac{1}{n^i} \frac{dt^i}{d\epsilon^m},$$

which implies that the change in group i ’s relative wealth is

$$\begin{aligned} \frac{d(\lambda^i n^i/n)}{d\epsilon^m} = & \frac{\lambda^i}{n} \left(\frac{dw\ell^i}{d\epsilon^m} - \frac{n^i}{n} \frac{dw\ell}{d\epsilon^m} \right) - \frac{\lambda^i}{n} \frac{1+i_{-1}}{P} (B_{-1}^i + \nu^i B_{-1}^g) \frac{d \log P}{d\epsilon^m} \\ & + \frac{\lambda^i}{n} \left(k_{-1}^i - \frac{n^i}{n} k_{-1} \right) \left(\frac{d\pi}{d\epsilon^m} + (1-\delta) \frac{dq}{d\epsilon^m} \right) + \frac{\lambda^i}{n} \frac{dt^i}{d\epsilon^m}, \quad (41) \end{aligned}$$

generalizing (21). The first term on the right-hand side summarizes the contribution of labor income, the second and third the contribution of financial wealth, and the fourth the contribution of transfers.⁴² Similar decompositions have been employed by Lueticke (2021) and other papers in the HANK literature to quantify the effects of redistribution on macroeconomic aggregates.

Using (40), Table VIII decomposes capital accumulation in the first period of the model simulation depicted in Figures 2-4.⁴³ There are two main takeaways. First, the redistribution towards a households drives the equilibrium increase in capital accumulation: $\left(\frac{n^a}{qk^a} \right) \left(q \frac{\partial k^a}{\partial n^a} \right) (d \log n^a)$ accounts for most of $d \log k^a$, and the latter in turn accounts for the aggregate capital accumulation. Second, the redistribution towards

⁴²We have already accounted for the transfers to households arising from the revaluation of government debt in the term involving $B_{-1}^i + \nu^i B_{-1}^g$, so that the transfers t^i here only refer to those from household birth and death given the model’s perpetual youth structure.

⁴³We multiply (40) by the size of the monetary shock simulated in Figures 2-4.

	<i>a</i>	<i>b</i>	<i>c</i>
$d \log k^i$	78bp	-188bp	0bp
$n^i/(qk^i)$	0.4	2.8	1.0
$q\partial k^i/\partial n^i$	1.9	0.7	0.0
$d \log n^i$	135bp	-25bp	35bp
$\partial \log k^i$	-24bp	-137bp	0bp

Table VIII: decomposing capital accumulation on impact of shock

Notes: decomposition of $d \log k^i$ depicted in Figures 2-4 uses (40) evaluated at 1,000 different points drawn from ergodic distribution of the state space and multiplies this identity by the size of the simulated monetary shock. *bp* denotes basis points (0.01%).

a households occurs at the expense of *b* households, implying that the redistribution which matters for these effects is *among* the wealthy who hold heterogeneous portfolios. In light of Table III, this also accords well with the view that the losers from a monetary expansion are wealthy retirees, as in Doepke and Schneider (2006).

Using (41), Table IX further clarifies the sources of redistribution towards *a* households.⁴⁴ The baseline parameterization indicates that the balance sheet revaluation towards these households via debt deflation,⁴⁵ higher profits on capital, and a higher price of capital together account for virtually all of their increase in relative wealth by 25bp. Redistribution via labor income and government transfers (as part of the model's perpetual youth structure) are small and in fact redistribute away from these households. Using alternative parameterizations, the remaining columns of Table IX further illuminate the model primitives governing redistribution via balance sheet revaluation. Each column only changes a single parameter from our baseline and simulates the same monetary policy shock.

The second column reports the results for an economy in which monetary policy shocks are persistent, setting $\rho^m = 0.75$, demonstrating the importance of redistribution through debt deflation. In that case, a monetary policy shock induces a stronger response of inflation relative to the baseline, as can be seen in the third row. The increase in the wealth share of *a* households thus increases to 39bp in the first row.

⁴⁴We again multiply by the size of the monetary shock simulated in Figures 2-4. Note $\frac{\lambda^a n^a}{n}$ is the wealth share inclusive of labor income, whereas s^a in Figure 3 is the financial wealth share alone.

⁴⁵We note that almost all of the redistribution through debt deflation owes to B^a (disciplined by the debt of these households in the SCF directly on balance sheet or via firm equity), rather than the indirect exposure through the government $\nu^a B^g$. This is because B^a is more than 15 times $\nu^a B^g$.

	Base	$\rho^m = 0.75$	$\chi^x = 0$	$\chi^W = 0$
$d(\lambda^a n^a/n)$	25bp	39bp	23bp	21bp
$(\lambda^a/n)(d[w\ell^a] - (n^a/n)d[w\ell])$	-1bp	-1bp	-1bp	-0bp
$(\lambda^a/n)(-(1+i_{-1})/P)(B_{-1}^a + \nu^a B_{-1}^g)d \log P$	20bp	33bp	23bp	22bp
$(\lambda^a/n)(k_{-1}^a - (n^a/n)k_{-1})d\pi$	1bp	1bp	1bp	0bp

Table IX: decomposing wealth redistribution to a households on impact of shock

Notes: decomposition of $d(\lambda^a n^a/n)$ depicted in Figures 2-4 uses (41) evaluated at 1,000 different points drawn from ergodic distribution of the state space and multiplies this identity by the size of the simulated monetary shock. bp denotes basis points (0.01%).

The third column eliminates the capital adjustment cost by setting $\chi^x = 0$, mitigating the redistribution through asset prices. In that case a monetary policy shock has no effect on the price of capital and therefore reduces the unexpected return on capital, as reported in the fifth row. There is a countervailing effect of a larger inflation response in the third row: the smaller adjustment cost amplifies capital accumulation which in turn amplifies the response in the labor market. Nonetheless, the increase in the wealth share of a households falls to 23bp in the first row.

The fourth column eliminates nominal wage rigidity by setting $\chi^W = 0$, demonstrating the role of changes in profit income in inducing redistribution across households. When wage rigidity is zero, the decline in the real wage and the stimulus to employment is essentially eliminated. It follows that the change in profits is negligible in the fourth row, which renders the change in the price of capital negligible in the fifth row. The increase in the wealth share of a households falls to 21bp even though the redistribution through debt deflation is again amplified in the third row.

4 Conclusion

In this paper we revisit monetary transmission in a New Keynesian environment with heterogeneous propensities to bear risk. An expansionary monetary policy shock lowers the risk premium if it redistributes to households with high MPRs. Heterogeneity in risk aversion, portfolio constraints, rules of thumb, background risk, or beliefs im-

ply redistribution in this way. In a calibration matching heterogeneity in the U.S. economy, this mechanism rationalizes the stock market responses to monetary policy which have eluded existing frameworks and amplifies its real effects.

The framework of this paper can be further developed along a number of dimensions. First, it seems fruitful to synthesize our perspective emphasizing assets' exposure to aggregate risk with the existing HANK literature emphasizing asset liquidity: in such a setting, an investor's MPR out of liquid versus illiquid wealth will differ, likely a better match to the micro data. Second, while we have focused for concreteness on the equity premium, a natural question is the extent to which our insights can explain the broader effects of monetary policy across asset classes, as in the Treasury market or foreign exchange market. Third, while our analysis has focused on the conditional responses to monetary policy shocks, it would be useful to examine the model's implied comovements between real activity and risk premia when featuring a richer set of business cycle shocks calibrated to the data. We leave these questions for future work.
